Review: calcium antagonists lead to a higher risk for myocardial infarction, congestive heart failure, and major cardiovascular events

QUESTION: In patients with hypertension, are calcium antagonists (CAs) as first line treatment superior, equal, or inferior to other antihypertensive drugs for reducing major cardiovascular events?

Data sources
Studies were identified by searching Medline up to September 2000, the US National Library of Medicine clinical trials database, and the Cochrane Library; by reviewing reference lists of identified articles; and by contacting colleagues.

Data extraction
Data were extracted on drug type and dose, patient characteristics, and main outcomes. Summary data were pooled.

Main results
9 trials involving 27,743 patients with about 120,000 person years of follow up met the selection criteria. CAs and other antihypertensive agents led to similar reductions in blood pressure. Patients assigned to diuretics, β blockers, angiotensin converting enzyme (ACE) inhibitors, or clonidine (n = 15,044) had a lower risk for myocardial infarction (MI), congestive heart failure, and major cardiovascular events than those allocated to CAs (n = 12,699) (table). No statistically significant differences were found for stroke or all cause mortality (table).

Conclusion
In patients with hypertension, initial treatment with calcium antagonists leads to higher risks for myocardial infarction, congestive heart failure, and major cardiovascular events than treatment with other antihypertensive agents.

Calcium antagonists (CAs) vs other antihypertensive agents in hypertension*

COMMENTARY

Bottom line interpretations of these 2 meta-analyses will vary depending on previous beliefs. For methodological purists and fans of CAs, the data neither prove nor refute the choice of CAs as first line agents for adults with hypertension or those at high risk for cardiovascular disease. For those of us who are already wary of using CAs as a first line treatment, the data support our practice of avoiding these agents. Many of us, regardless of our previous beliefs, may now question whether we should either begin reserving or using CAs specifically for people who have high risk for stroke. Such a decision would be premature for at least 2 reasons. Firstly, we cannot reliably determine whether an individual is likely to have a stroke and no cardiac outcomes. Secondly, the important meta-analyses summarised here are limited and complicated.

The meta-analyses have limited power to precisely assess stroke and cardiac outcomes because few large, long term trials exist that directly compare the effects of different antihypertensive agents. They are complicated because they combine data from trials characterised by either discontinuation of initial antihypertensive drug treatments or the addition of second and third antihypertensive agents. They make comparisons by grouping all drugs within a class together (eg, CAs) as well as by grouping drugs across classes together (eg, diuretics and β blockers). This method is dicey because all antihypertensive drugs have actions other than that of lowering blood pressure, and mechanisms by which a drug lowers blood pressure probably have effects independent of the blood pressure lowering effect.1 Moreover, mechanisms of action and effects may vary among antihypertensive drugs within classes as well as across classes.
Review: ACE inhibitors, calcium antagonists, and more intensive blood pressure lowering strategies reduce cardiovascular events

QUESTION: In patients with hypertension, diabetes mellitus, coronary artery disease (CAD), or renal disease, what are the effects of angiotensin converting enzyme (ACE) inhibitors, calcium antagonists (CAs), and other blood pressure lowering drugs on mortality and major cardiovascular morbidity?

Data sources
In 1995, a registry was established of all large scale trials that were in progress or in advanced stages of planning.

Study selection
Studies were selected if there was a randomised comparison between patients allocated to a blood pressure lowering drug and placebo or to another active antihypertensive agent or to a blood pressure lowering strategy that had a different intensity. Trials had to have a minimum of 1000 patient years of follow up planned and must not have been published before July 1995.

Data extraction
Data were extracted on patient characteristics, discontinuation rates, blood pressure, and major outcomes. Individual patient data or summary data were combined.

Main results
Data from 15 trials (74,696 patients, mean age 62 y, 53% men) were included. Combining data from 4 placebo controlled trials of ACE inhibitors showed that active treatment led to relative reductions of 20% to 30% in stroke, CAD, and major cardiovascular events. Combining data from 3 trials that compared ACE inhibitors with diuretics or β blockers showed no differences between the agents for any outcome. Combining data from 5 trials that compared CAs with diuretics or β blockers showed a slightly lower risk of stroke and a slightly higher risk of CAD with CAs (table).

Conclusions
In patients with hypertension, diabetes mellitus, coronary artery disease, or renal disease, angiotensin converting enzyme inhibitors and calcium antagonists are more beneficial than placebo. Calcium antagonists lead to a lower risk for stroke but to a slightly higher risk for coronary artery disease than diuretics or β blockers.

COMMENTARY—continued from previous page

The reviews include trials that involved various groups of patients with different risks for cardiovascular disease. Pathways that lead with diabetes, renal disease, hypertension, or CAD to experience cardiovascular outcomes may differ. Antihypertensive agents may have specific effects on causal pathways unique to particular groups of patients. Generalising the results of meta-analyses that are based on few trials is potentially misleading: 1 or 2 large trials that tested a specific drug in a particular population could drive the results. The determinants of cause specific outcomes, such as stroke and CAD, probably differ, even among people who share common risk factors (eg, patients with hypertension). Although such drugs as CAs may differentially affect pathways that lead to strokes from those that lead to CAD, meta-analyses based on few trials cannot easily disentangle specific from class effects of antihypertensive drugs. Finally, the reviews are limited because they do not address the side effects and costs of different drugs.

Regardless, both meta-analyses are important summaries of accumulating evidence. Some diuretics, β blockers, ACE inhibitors, and CAs have proven morbidity and mortality benefits for some people with hypertension or some who are at high risk for cardiovascular disease. Knowledge about the relative benefits and harms of the different drugs in particular groups of patients is murky but will probably become clearer in the next 5 years as larger trials that directly compare antihypertensive agents become available.

Review: calcium antagonists lead to a higher risk for myocardial infarction, congestive heart failure, and major cardiovascular events
