The two-step Fagan’s nomogram: ad hoc interpretation of a diagnostic test result without calculation

Charles G B Caraguel,¹ Raphaël Vanderstichel²

Abstract

In 1975, Fagan published a nomogram to help practitioners determine, without the use of a calculator or computer, the probability of a patient truly having a condition of interest given a particular test result. Nomograms are very useful for bedside interpretations of test results, as no test is perfect. However, the practicality of Fagan’s nomogram is limited by its use of the likelihood ratio (LR), a parameter not commonly reported in the evaluation studies of diagnostic tests. The LR reflects the direction and strength of evidence provided by a test result and can be computed from the conventional diagnostic sensitivity (DSe) and specificity (DSP) of the test. This initial computation is absent in Fagan’s nomogram, making it impractical for routine use. We have seamlessly integrated the initial step to compute the LR and the resulting two-step nomogram allows the user to quickly interpret the outcome of a test. With the addition of the DSe and DSP, the nomogram, for the purposes of interpreting a dichotomous test result, is now complete. This tool is more accessible and flexible than the original, which will facilitate its use in routine evidence-based practice. The nomogram can be downloaded at: www.adelaide.edu.au/vetsci/research/pub_pop/2step-nomogram/.

Introduction

Collecting and interpreting evidence, both clinical and analytical, is essential to the diagnostic process. This evidence may or may not support the likelihood of a patient having a given condition, depending on the nature and strength of the evidence. In practice, the range of collectable evidence is wide and includes patient profile, exposure history, symptoms and clinical or laboratory test results. In the context of evidence-based medicine, the probability of a patient having a condition of interest, given the evidence collected, should be objectively quantified. This probability is referred to as the posterior (post-test) probability of having the condition or, in conventional epidemiology, the predictive value. However, the calculations for predictive values, derived from Bayes’ theorem, are tedious and rarely performed in practice.¹ ²

Fagan’s nomogram

In 1975, Dr Terrence J. Fagan¹ integrated Bayes’ theorem into a nomogram for practitioners to quantify the post-test probability that an individual is affected by a condition given an observed test result and given the probability of the individual having the condition before the test was run (pretest probability). The Fagan’s nomogram is widely recognised as a convenient graphical calculator and is frequently referenced in evidence-based medicine and clinically applied epidemiology textbooks.⁴ ⁵ To use the Fagan’s nomogram (as depicted in figure 1), a line must be drawn from the estimated pretest probability (left axis) through the likelihood ratio (LR) of the observed test result (centre axis) and the intersection of the line with the right axis provides the post-test probability. Regrettably, its routine use seems to be limited by the unfamiliarity of practitioners with the concept of diagnostic LRs,⁶ and also because LR estimates are rarely reported in studies evaluating diagnostic tests.⁷

LR of a test result

The LR represents the direction and the strength of evidence provided by a test result. It is calculated by dividing the likelihood of the test result among patients with the condition by the likelihood of the same test result among patients without the condition.⁸ The values of the LR range from zero to infinity. When the LR is greater than one, the test result supports the presence of the condition (individuals with the condition are more likely to have the given test result than individuals without the condition), while, when it is lower than one, the test result supports the absence of the condition (individuals with the condition are less likely to have the given test result than individuals without the condition). An LR of one suggests that the observed test result has no diagnostic value. The farther the LR is away from one (towards zero or infinity), the stronger the evidence is provided by the test.

LRS can be estimated for binary (positive or negative), ordinal (more than two categories) or continuous (number scale) diagnostic test outcomes. However, ordinal and continuous outcomes are often dichotomised using a cut-off value to help with the decision-making process,⁹ and validation studies for diagnostic tests conventionally report the corresponding diagnostic sensitivities and specificities (DSe and DSP, respectively), not LRs.⁷ For a test with a binary outcome, two LRs are reported, one for a positive test result (LR⁺) and one for a negative test result (LR⁻). The LR⁺ and LR⁻ can be directly computed from the test DSe and DSP (LR⁺=DSe/(1−DSP) and LR⁻=(1−DSe)/DSP, respectively).

The two-step Fagan’s nomogram

The original version of the Fagan’s nomogram first requires the calculation of the LRs of the test result from the accessible DSe and DSP. The two-step Fagan’s nomogram, proposed here, includes the initial calculation step for the LR⁺ and LR⁻, while maintaining the structure of the original nomogram (figure 2); it was generated using the Python-based program PyNomo,¹⁰ and the script is available from the corresponding author upon request.

User’s guide for the two-step Fagan’s nomogram

As compared to the original Fagan’s nomogram (figure 1), the updated version includes two additional axes...
corresponding to the DSe and the DSp of the test (Figure 2). The DSe and the DSp axes have red (left-hand side) and blue (right-hand side) scales that are used, respectively, to calculate the LR of a positive or a negative test result as a first step. The second step corresponds to the traditional Fagan’s approach where the test result probability is deducted from the previously obtained LR and the pre-test probability.

Step 1: calculation of the LR of a given test result

It is first necessary to know the DSe and DSp of the test (from the manufacturer or the literature) and to have obtained a test result from the patient (ie, positive or negative). If the obtained test result is positive, the red scales on the DSe/DSp axes must be used, whereas, if the test result is negative, the blue scales should be used. A line is drawn to connect the appropriate DSe and DSp axes, and the LR is calculated using the formulae:

\[
LR^+ = \frac{DSe}{1 - DSp}
\]

and

\[
LR^- = \frac{1 - DSe}{DSp}
\]

Given that the patient came from a high-risk population with an estimated prevalence of 2%, if this patient tests positive, the post-test probability that she truly has cancer would be approximately 28% (red line). Alternatively, if the patient tests negative, the post-test probability that she truly has cancer would be approximately 0.6% (blue line).
values for the test and the intersection of the line with
the central axis provides the LR of the obtained test
result.

At this stage, the user can appreciate the direction
and strength of the evidence provided by the test
result, regardless of the pre-test probability. If the LR
of the test result is greater than one and very large, the
evidence provided by the test result strongly supports
the presence of the condition. However, if the LR of
the test result is smaller than one and very close to zero,
the evidence provided by the test result strongly sup-
ports the absence of the condition. Naturally, if the LRs
for the test are reported or available, this first step is
not necessary.

Figure 2  The two-step Fagan’s nomogram. For example: the MRI screening test for breast
cancer in high-risk female patients has an estimated diagnostic sensitivity of 75% and
specificity of 96%.11 A positive result from the MRI provides a likelihood ratio (LR+) of
approximately 19 (red line, I). Given that the patient came from a high-risk population with an
estimated prevalence of 2% and tested positive, the post-test probability for this patient to truly
have cancer would be approximately 28% (red line, II). Alternatively, a negative test result would
produce a likelihood ratio (LR−) of approximately 0.25 (blue line, I) and the post-test probability
for this patient to truly have cancer would be approximately 0.6% (blue line, II).
Step 2: calculation of the post-test probability

The second step corresponds to the original use of the Fagan’s nomogram. Given an estimate for the pre-test probability, a second line is drawn from the pre-test probability estimate on the far left axis through the previously obtained estimate of the LR on the central axis (from Step 1). The intercept of this line with the far right axis provides the corresponding post-test probability of the individual.

Example

The example of MRI screening for women at high risk for breast cancer is used here to illustrate the application of the two-step Fagan’s nomogram (eg, figure 2). A meta-analysis, using data from 11 MRI evaluation studies, reported estimates for the DSe and DSp at 75% and 96%, respectively.11

In the instance where the MRI yields a positive screening result for at least one breast of a patient (red scales used for the DSe and DSp axes, figure 2), the line produced in the first step indicates an LR+ of approximately 19 (red line #1, figure 2). The LR+ is greater than one and quite large indicating that a positive result from the MRI supports the likelihood of a cancer being present. Subsequently, based on an estimated prevalence of 2% for breast cancer in these high-risk patients,1 the intercept of the line produced in the second step indicates that the probability for the patient to have breast cancer increased from approximately 2 to 28%, given the positive MRI result for this patient (red line #2, figure 2). Estimates of the prevalence are not always available in the literature for all the health conditions. In these instances, it is a common practice to use best guess estimates from clinical experience.

Alternatively, if the MRI yields a negative screening result for both breasts (blue scales used for the DSe and DSp axes, figure 2), the line produced in the first step indicates an LR− of approximately 0.25 (blue line #1, figure 2). The LR− is smaller than one and is close to zero indicating that a negative result from the MRI does not support the likelihood of a cancer being present. Subsequently, based on the previous 2% prevalence estimate, the intercept of the line produced in the second step indicates that the probability for the patient to have breast cancer decreased from approximately 2 to 0.6%, given the negative MRI result for this patient (blue line #2, figure 2).

Conclusion

The Fagan’s nomogram is the simplest of the Bayes’ theorem calculators to help practitioners determine the probability of a patient truly having a condition of interest given a particular test result.4 It is particularly useful for the clinical practice when speed is favoured over precision without the need of a calculator or computer.12 However, its practicality at the bedside is limited because the initial computation of the LR, from the DSe and DSp, is missing. With the addition of this first step, the two-step Fagan’s nomogram is expected to facilitate the interpretation of any test outcome (positive or negative) and enhance its utilisation for routine use by evidence-based practitioners. The Bayes’ theorem, and thus the nomogram, is the proper approach to interpret the result from one test at a time, however, users should be cautious when interpreting multiple results from a chain of tests (eg, history, clinical examination, etc.). Unless the tests used in the chain are shown to be conditionally independent (ie, the result of one test does not depend on the result of the other test given the health status), it is not recommended to use the post-test probability from one test result as the pre-test probability for the subsequent test. The two-step Fagan’s nomogram can be downloaded at: www.adelaide.edu.au/vetsci/research/pub_pop/2step-nomogram/.
