Context
Despite the increasing number of effective disease modifying therapies for multiple sclerosis (MS), there are no effective therapies for the progressive, neurodegenerative phase of the disease. There is now abundant experimental evidence that cannabinoids and the endocannabinoid system are protective factors in animal models of MS and also other neurodegenerative conditions. This randomised controlled trial (RCT) aimed to investigate the potential neuroprotective properties of the prototypical cannabinoid Δ9-tetrahydrocannabinol (THC) as measured by the slowing of the progressive phase of MS, based on data from animal models of MS1 and also clinical findings from an earlier study by the same group investigating the efficacy of THC as a spasticity alleviating therapy in MS.

Methods
Four hundred and eighty-nine eligible patients were enrolled in this blinded multicentre RCT, 332 received active treatment (oral dronabinol/THC at maximal dose of 28 mg/day) and 166 received placebo (vegetable oil capsules). Primary clinical outcome measures were: time to confirmed Extended Disability Status Scale (EDSS) score progression (physician based) at 3, 6 then 6 monthly up to 36 months unless progression was seen at this time when a further assessment was scheduled at 42 months and change in Multiple Sclerosis Impact Scale–29 (MSIS–29) score (patient based). Randomisation was balanced according to the EDSS score, study site and disease type and allocation of the randomisation scheme was concealed.

Findings
The study failed to demonstrate slowing of progressive disease on primary (time to confirmed EDSS score progression and MSIS–29) or secondary outcome measures (clinical and MRI measurement of brain atrophy). A treatment effect on slowing of progression rate was detected in a subgroup of patients (114 in active group, 46 in placebo group) with initial EDSS scores 4–5.5.

Commentary
This study highlights the problems in designing trials to investigate potential neuroprotective therapies in neurodegenerative conditions such as MS. It is clear from the results of this study that the inclusion of people with MS with an EDSS of 6 and above is problematic as, stated also by the authors, the EDSS is not linear and patients tend to spend considerably more time at EDSS 6–6.5 whereas progression through grades 4–5.5 tends to be more rapid. Clearly patients with EDSS scores of 6 and above are unlikely to be sensitive to a treatment effect during the typical course of this type of study (3–4 years) and there was a lower than expected progression rate observed in this study which may have affected the ability to detect clinical change, which would require longer trials.

While it was clear that daily THC, at the doses tested, did not slow progression it is of immense interest that analysis of a subset of people with MS with an EDSS 4–5.5 demonstrated that THC significantly (p≤0.01) did slow disease progression but numbers were insufficient for firm conclusions to be drawn.

Individuals with lower levels of disability should be considered for study in future clinical trials for neuroprotective therapies in MS, and thus, this study has performed a valuable service in indicating better trial design for future studies. However, the likelihood of further funding being obtained to perform a further RCT investigating the neuroprotective properties of cannabinoids may be unlikely and so a promising potential therapy for progressive MS may be lost.

Furthermore, although the trial was not designed for symptom control, it failed to demonstrate any impact on spasticity and so did not provide replication of the result on which the study rationale was based.

Implications for practice
This study does not provide evidence for a change in current practice, but it does indicate that in some patients THC can act as a neuroprotective agent, which requires further study to confirm this finding.
