**Influenza vaccination of healthy adults was effective during the 1998–9 flu season but not the 1997–8 season**

**QUESTION:** Is influenza vaccination effective for preventing influenza-like illness (ILI) in healthy working adults?

**Design**
Randomized (allocation concealed*†), blinded (patients and clinicians),* controlled trial done during the flu seasons of 1997–8 and 1998–9.

**Setting**
Dearborn, Michigan, USA.

**Participants**
2575 healthy adults who were 18–64 years of age, were full time employees of the Ford Motor Company, and did not have any medical condition for which influenza vaccine was recommended or any contraindications to vaccination. 1184 adults (mean age 44 y, 79% men) participated during 1997–8, with 95% follow up, and 1191 (mean age 44 y, 76% men) participated during 1998–9, with 99% follow up.

**Intervention**
During the 1997–8 flu season, 595 adults were allocated to trivalent inactivated influenza vaccine, and 589 were allocated to a placebo injection of sterile saline. During the 1998–9 season, 587 were allocated to influenza vaccine, and 604 were allocated to placebo.

**Main outcome measures**
Patient reports of ILI (feverishness or temperature ≥100°F plus cough or sore throat) and associated physician visits and lost work days during the influenza period.

**Main results**
During 1997–8, vaccine efficacy was 86% (table). Vaccine recipients reported 38% more ILI related sick days (p = 0.01), 45% more lost work days (p = 0.047), and 378% more lost work hours for physician visits (p < 0.001) than placebo recipients; ILIs and physician visits did not differ. During 1998–9, vaccine efficacy was 80% (table). Vaccine recipients reported 34% fewer ILIs and 34% fewer related sick days (p < 0.001 for both), 42% fewer physician visits (p < 0.001), 32% fewer lost work days (p = 0.002), and 47% fewer lost hours for physician visits (p < 0.001).

**Conclusion**
Influenza vaccination did not prevent influenza-like illness in healthy working adults during the 1997–8 flu season but was effective during the 1998–9 flu season.

**COMMENTARY**

Influenza vaccination is clinically effective and cost effective in older people.1 Using relatively conservative estimates of 40% for reducing admission to hospital and death, influenza vaccination results in a savings of US $2.92 per Medicare beneficiary.3 Furthermore, the cost per year of life gained is $145. These savings were calculated by subtracting hospital payment savings (for admission for pneumonia treatment) from vaccine programme costs.

Admission to hospital for influenza, is rare, however, in young, healthy adults, so cost effectiveness is harder to determine. Economic benefits are calculated by balancing the increased costs of vaccination (because of the need to take time off from work) with direct (physician visits and prescriptions) and indirect costs (lost time from work) from an influenza illness.

A previous randomised trial by Nichol et al suggested that vaccination of healthy, working adults would save $47 per vaccinee.2 This analysis was limited by a relatively high calculated influenza attack rate (35%) that was determined by telephone interviews.4 To determine the generalisability of Nichol’s findings, Bridges et al studied the clinical effectiveness and societal cost benefit of influenza vaccination over a 2 year period. Influenza infection was laboratory confirmed in a subset of patients. In the first year of the study, the vaccine and the most common circulating influenza virus were a poor match; this problem occurs about once every 10 years. Influenza vaccination provided neither clinical nor economic benefit in that year. In the second year of the study, vaccine efficacy was 86% (well in line with the typical 70% to 90% efficacy rate) with a more characteristic attack rate of 16%. Even in this year, vaccinating young, healthy adults against influenza resulted in a net cost of about $11 per vaccinee.

These data verify the clinical benefits of influenza vaccination, so physicians may confidently recommend vaccination for “any person who wishes to reduce the likelihood of becoming ill with influenza.”5 Unfortunately, no net societal economic benefit may be derived from vaccinating young, healthy people. Sometimes doing the right thing costs us money.
